### Abstract

Colorectal cancer is the second leading cause of cancer-related death in the United States and is a primary cause of morbidity and mortality throughout the world. Although the majority of colorectal cancer case causes remains unclear, it's progression has been linked to colonic bacterial community composition. Viruses are another important component of the colonic microbial community that have yet to be studied in colorectal cancer, despite their oncogenic potential. We evaluated the colorectal cancer virome (virus community) using a cohort of 90 human subjects with either healthy, adenomatous (precancerous), or cancerous colons. We utilized 16S rRNA gene, whole shotgun metagenomic, and purified virus metagenomic sequencing methods to compare the colorectal cancer virome to the bacterial community. We found that alpha and beta diversity metrics were insufficient for detecting virome changes in colorectal cancer, but more sophisticated virome-based random forest models identified significant changes in the virus community. The majority of the cancer-associated virome consisted of temperate bacteriophages, suggesting the community was indirectly linked to colorectal cancer by modulating bacterial community structure and functionality. These results provide foundational evidence that bacteriophage communities are associated with colorectal cancer and likely impact cancer progression by altering the bacterial host communities. Together our findings add to the existing model for the role the microbiome plays in colorectal cancer development, thus providing us with a more complete understanding of colorectal cancer etiology.

Word Count: 226

# Significance Statement

Colorectal cancer is a leading cause of cancer-related death in the United States and worldwide. Its progression

and severity have been linked to colonic bacterial community composition. Little is known about cancer-

associated colon virus communities and their influence on bacteria. We began addressing this knowledge

gap by identifying changes in colonic virus communities in colorectal cancer patients, and how they compare

to bacterial community changes. The altered colorectal cancer virome was used in virome-based machine

learning models to accurately classify patient cancer status. The cancer-virus classifier was driven primarily

by bacteriophages (bacterial viruses). Wider phage host ranges were more strongly associated with colorectal

cancer. The results suggest an indirect role for the virome impacting colorectal cancer by modulating their

associated bacterial community.

### 53 Introduction

Due to their mutagenic abilities and their propensity for functional manipulation, human viruses are strongly associated with, and in many cases cause, cancer (1-4). Because bacteriophages are crucial for bacterial community stability and composition (5-7), and because bacteria have been implicated as oncogenic agents (8-10), bacteriophages have the potential to indirectly impact cancer. The gut virome (the virus community of the gut) therefore has the potential to impact health and disease (e.g. cancer), and has been associated with diseases including periodontal disease (11), HIV (12), antibiotic exposure (13, 14), urinary tract infections (15), and inflammatory bowel disease (16). The precedence of the virone impacting human health and the strong association of bacterial communities with colorectal cancer suggest that colorectal cancer may be linked to altered virus communities. Colorectal cancer is the second leading cause of cancer-related deaths in the United States (17). The US National Cancer Institute estimates over 1.5 million Americans have been diagnosed with colorectal cancer in 2016, and over 500,000 Americans will have died from the disease (17). Although the majority of colorectal cancer case causes remains unclear, variation in colorectal bacterial communities have been linked to the disease (8, 10, 18, 19). This work has led to the proposal of disease models in which bacteria colonize the colon, develop biofilms, promote infiltration, and enter an oncogenic synergy with the cancerous human cells (18). This association has also allowed researchers to leverage bacterial community signatures as biomarkers to provide accurate, noninvasive colorectal cancer detection from stool (8, 20). While an understanding of colorectal cancer bacterial communities has proven fruitful both for disease classification and understanding 71 underlying etiology, bacteria are only a subset of the colon microbiome. Viruses are another important 72 component of the colon microbial community that have yet to be studied in the context of colorectal cancer. We evaluated colorectal cancer disruptions in virus and bacterial community composition in a human cohort whose stool was sampled at the three relevant stages of cancer development: healthy, adenomatous, and cancerous. Colorectal cancer is a stepwise process that begins when healthy tissue develops into a precancerous polyp (i.e. adenoma) in the large intestine (21). If left untreated, the adenoma will develop into a cancerous lesion that can invade and metastasize, leading to severe illness and death. Progression to cancer can be prevented when precancerous adenomas are detected and removed during routine screening (22, 23), and survival for colorectal cancer patients may exceed 90% when the lesions are detected early and removed (22). Thus work such as this, which aims to power early detection and prevention of progression from early cancer stages, has a great potential to inform therapeutic development.

In this study we report that colorectal cancer is associated with variation in colonic virus communities. The majority of viruses identified within the virome were temperate bacteriophages. Just as the association between the bacterial community and colorectal cancer was driven by select influential bacteria including Fusobacterium, the association between the virome and colorectal cancer was also driven by a subset of influential phages. Our data suggest that the influential phages do not exclusively infect influential bacterial (e.g. Fusobacterium phages infecting the Fusobacterium), but rather act through the community as a whole. The implications of these findings are threefold. First, this supports a biological role for the virome in colorectal cancer development and suggests that more than bacteria are involved in the process. Second, we present a supplementary, or even alternative virus-based approach for classification modeling of colorectal cancer using stool samples. Third, we provide initial support for the importance of studying the virome as a component of the microbiome ecological network, especially in cancer.

### 95 Results

S4).

112

#### The Colorectal Cancer Virome Cohort

and 30 which had carcinomas (Figure S1). Half of the stool was used to sequence the bacterial communities using both 16S rRNA gene and shotgun sequencing techniques. The other half of the stool samples were purified for virus like particles (VLPs) and consequent genomic DNA extraction, followed by shotgun metagenomic sequencing. The VLP purification allowed us to observe the active virone because we only 101 sequenced those viruses that are encapsulated. Virus DNA was purified before sequencing, which allowed us to analyze DNA from within virus capsids (Figure S1). Each extraction protocol was performed with a blank control to detect any contaminants from 104 reagents. Only one of the nine controls contained detectable DNA, which was of a minimal concentration, thus providing initial evidence of successful sequencing of VLP genomic DNA over potential contaminants 106 (Figure S2 A). As was expected, these controls were sparsely sequenced and were mostly removed while sub-sampling to even depths (Figure S2 B). The high quality phage and bacterial sequences were assembled 108 into highly covered contigs longer than 1kb (Figure S3). Because contigs only represent genome fragments, we further clustered related contigs into operational genomic units (OGUs; conceptually similar to 16S rRNA 110 gene operational taxonomic units) with the majority containing hundreds of related contigs (Figure S3 -111

The study cohort consisted of 90 human subjects, 30 of which had healthy colons, 30 of which had adenomas,

### 113 Virus Diversity and Colorectal Cancer

- Microbiome and disease associations are often described as being of an altered diversity (i.e. "dysbiotic").
- We therefore initially evaluated the diversity of virome OGUs and their association with colorectal cancer.
- We utilized the Bray-Curtis dissimilarity metric to evaluate differences in communities between disease states.
- To control for uneven sequencing depths, we subsampled to a minimum depth that maintained most samples
- while excluding the sparsely sequenced blank controls.
- 119 We calculated the differences in virus alpha diversity associated with colorectal cancer. We found no significant
- alterations in either Shannon entropy or richness (Figure S5 C-D). There was also no statistically significant
- clustering of the disease groups (ANOSIM p-value = 0.432, Figure S5). It is worth noting that there was a
- significant difference between the blank controls (those few that remained after sub-sampling) and the other
- study groups, further supporting the quality of our sample set (Anosim p-value =  $7.18 \times 10$ -28, **Figure S6**).
- Overall, standard diversity metrics were insufficient for capturing the differences in the virus communities
- between disease states.

### Virome Composition Changes in Colorectal Cancer

- Previous work has shown that 16S rRNA gene relative abundance profiles are effective features for classifying
  - stool samples as originating from healthy, adenomatous, or cancerous individuals (8, 20). The exceptional
- 129 performance of bacteria in these classification models supports a role for bacteria in colorectal cancer. Here
- we built off of these findings by evaluating the ability of virus community signatures to classify stool samples
- 131 and compared performance to models built using bacterial community signatures.
- We built and tested random forest models to classify stool samples as belonging to either cancerous or healthy
- individuals. These models were based on virus metagenomic community or bacterial 16S rRNA gene relative
- abundance profiles. We confirmed that our bacterial 16S rRNA gene model replicated the performance of
- the original report which used logit models instead of random forest models (Figure 1 A) (8). We then
- compared the bacterial 16S rRNA gene model to a model built using virome relative abundance. The viral
- model performed as well as the bacterial model (corrected p-value = 0.964) with the viral and bacterial
- models achieving mean AUC (area under the curve) values of 0.807 and 0.799, respectively (Figure 1 A -
- 139 B).
- To evaluate the synergistic capabilities of the bacteria and viruses within the model, we built a combinatory
- model that used both bacterial and viral community data. The combination model yielded modest but

significantly improved performance beyond the separate virome (corrected p-value =  $2.06 \times 10$ -4) and bacterial (corrected p-value =  $9.33 \times 10$ -5) models, and yielded an AUC of 0.838 (Figure 1 A - B). This suggested that features from the virus and bacterial communities may have had synergistic capabilities for classifying stool as belonging to cancerous individuals.

We also compared these models to relative abundance profiles from bacterial metagenomic shotgun sequencing
data. This model performed poorly, with a mean AUC of 0.488 (Figure 1 A - B). Further investigation
revealed that the bacterial 16S rRNA gene model was strongly driven by sparse and lowly abundant OTUs
(Figure S7). Filtration of OTUs with a median abundance of zero resulted in the removal of six OTUs, and
a loss of model performance down to what was observed in the metagenome (Figure S7 A). The majority
of these OTUs had a relative abundance lower than 1% (Figure S7 B).

The association between the two communities and colorectal cancer was driven by a few important microbes, 152 measured using the mean decrease in model accuracy when each was removed. Fusobacterium was the primary driver of the bacterial association with colorectal cancer, which is consistent with its previously described 154 oncogenic potential (Figure 1 C)(18). The virone signature was also driven by a few operational genomic 155 units, suggesting a role for the OGUs in cancer development (Figure 1 D). The identified viruses were 156 bacteriophages, belonging to Siphoviridae, Myoviridae, and orphan phage taxa without taxonomic identifiers 157 (denoted "unclassified"). Many of the important viruses were unidentifiable (denoted "unknown"), suggesting 158 they are members of the abundant unknown viral population associated with the human virome. This is 159 common in the virome; studies can have as much as 95% of virus sequences belong to unknown genomic units (24, 25). When the bacterial and viral community signatures were combined, both bacterial and viral 161 organisms drove the community association with cancer (Figure 1 E).

#### Phage Influence Shifts During CRC Progression

Because our cohort included healthy, adenomatous, and cancerous colons, we were able to gain insight into virus community shifts during cancer progression. We evaluated community shifts between the two disease transitions (healthy to adenomatous and adenomatous to cancerous) by building random forest models to compare only the sample classes around the transitions. We found that, while bacterial 16S rRNA gene models perform equally well for all disease class comparisons, the virome models performed worse when seperating healthy from adenomatous, and better when seperating adenomatous from cancerous (Figure S8 A-B). Like bacteria (Figure S8 F-H), different virome members drove the transitions from healthy to adenomatous and adenomatous to cancerous, with one phage exception (Figure S8 C-E). A Myoviridae OGU (Cluster

188) was the seventh most important phage driving the transition from a healthy to adenomatous state, and
was the most important phage driving the progression from an adenomatous to carcingenic state. Therefore,
like bacteria, there are distinct phages assocaited with the transitions from a healthy to an adenomatous
colon, and from an adenomatous to a cancerous colon.

### 176 Inclusive Colonic Virome Classification

After evaluating our ability to classify samples between two disease states, we performed a comprehensive three-class classification of all three disease states. We used a three-class random forest model for the bacterial 16S rRNA gene and viral sample sets. The bacterial signature model yielded an AUC of 0.779 and outperformed the viral community model which yielded an overall AUC of 0.698 (p-value = 1.08 × 10-5, Figure S9 A-C). Both models were best able to classify cancer samples from healthy or precancerous samples, but struggled to distinguish adenomatous from healthy or cancerous (Figure S9 A-B). The cancerous signal was the most discriminatory of the three sample types.

The microbes important for the cancer vs healthy and healthy vs adenoma bacteria and virus models were also important for the three-class model (Figure S9 D-E). The most important bacterium was the same Fusobacterium between the two and three class models, supporting its significance to the association between cancer and the bacterial communities (Figure 1 C, Figure S9 D). The viruses most important to the three-class model were identified as bacteriophages (Figure 1 D, Figure S9 E).

The classification model determined cancer state by incorporating the relative abundance profiles of the microbes within each community. The signatures ranged from notably high abundance of some OGUs, low abundance of some OGUs, and an absence of other OGUs (**Figure S9 F**). Not all important OGUs were of increased abundance. The viral classification model depended on the unique signatures of these different abundance profiles to accurately classify each sample.

#### Dominance of Bacteriophages in Colorectal Cancer Virome

Changes in the colorectal cancer virome could have been driven directly by eukaryotic viruses or indirectly by bacteriophages acting through their bacterial hosts. To better understand the types of viruses that are important for colorectal cancer, we identified the virome OGUs as being similar to either eukaryotic viruses or bacteriophages. The most important viruses to the classification model were identified as bacteriophages (Figure S9). Overall we were able to identify 78.8% of the OGUs as known viruses, and 93.8% of those viral

200 OGUs aligned to bacteriophage reference genomes.

We evaluated whether the phages in the community were primarily lytic (replicate by lysing their host) or 201 temperate (lysogenic; able to integrate into their host's genome, as well as lyse the cell). We accomplished this by identifying three markers for temperate phages in the OGU representative sequences: 1) presence of 203 phage integrase genes, 2) presence of known prophage genes, according the the ACLAME (A CLAssification of Mobile genetic Elements) database, and 3) nucleotide similarity to regions of bacterial genomes. This 205 approach was done as described in previous work (25, 26). We found that the majority of the colon phages were temperate, and that the overall fraction of temperate phages remained consistent throughout the 207 healthy, adenomatous, and cancerous stages (Figure S10 E). Thus the majority of the OGUs are temperate bacteriophages and not eukaryotic viruses, indicating the association between the virome and colorectal 209 cancer is reliant on bacteriophage communities that can lie dormant in bacterial genomes. These findings are 210 consistent with previous reports suggesting the gut virome is primarily temperate phages (12, 16, 26, 27). 211

### 212 Community Context of Influential Phages

Because the link between colorectal cancer and the virome was driven by bacteriophages, we hypothesized that
the influential phages were predators of the influential bacteria, and thus influenced their relative abundance
through predation. If this hypothesis were true, we would expect the relative abundance between important
bacteria and phages to be correlated. Instead we observed a strikingly low correlation between the bacterial
and phage relative abundances (Figure 2 A,C). There was an overall absence of correlations between the
most influential phage OGUs and bacterial OTUs (Figure 2 B). This evidence supported our null hypothesis
that the influential phages are not primarily predators of influential bacteria.

Our next hypothesis was that the influential phages were acting by infecting a wide range of bacteria in the 220 overall community, instead of just the select influential bacteria. This hypothesis would be supported by showing that the influential bacteriophages were community hubs within the bacteria and phage interactive 222 network. We investigated the infectious capabilities and potential host ranges of the influential phages by building a machine learning model to predict which phage OGUs infect which bacteria in the overall 224 community. The predicted interactions were then used to build a network which was used for subsequent analysis, as has been previously described (Cite Network Preprint). This analysis revealed a wide tropism 226 range for the bacteriophages within the community (Figure 3 A). We calculated the alpha centrality 227 (measure of importance in the ecosystem network) of each phage OGU's connection to the rest of the network, and compared the centrality to the importance of each OGU in the colorectal cancer classification model. 229

We found that phage OGU centrality is significantly positively correlated with importance to the disease model (p-value = 0.0173, rho = 0.14), indicating that phages important in driving colorectal cancer were also community hubs (Figure 3 B). Together these findings supported our hypothesis that influential phages were hubs within their microbial communities.

### 34 Discussion

Because of their propensity for mutagenesis and capacity for modulating their host functionality, many viruses are oncogenic (1–4). Because some bacteria also have oncogenic properties, bacteriophages may play an indirect role in promoting carcinogenesis by altering bacterial communities (8–10). Despite their carcinogenic potential and the strong association between bacteria and colorectal cancer, the link between virus colorectal communities and colorectal cancer has yet to be evaluated. Here we show that, like colonic bacterial communities, the colon virome is associated with colorectal cancer. Our findings support a working hypothesis for oncogenesis by phage-modulated bacterial community composition.

Together our data allowed us to begin modeling the role the colonic virome played in colorectal cancer. (Figure 4.4.) We found basic diversity metrics of alpha diversity (richness and Shannon entropy) and beta

(Figure 4 A). We found basic diversity metrics of alpha diversity (richness and Shannon entropy) and beta 243 diversity (Bray-Curtis dissimilarity) were insufficient for identifying virome community changes between healthy and cancerous states. By implementing a more sophisticated machine learning approach (random 245 forest classification), we detected strong associations between the colon virus communities and colorectal cancer. Colorectal cancer was primarily associated with altered bacteriophage communities. These phage 247 communities were not exclusive predators of the most influential bacteria (e.g. Fusobacterium linked to 248 decreases in Fusobacterium phages), as demonstrated by the lack of correlation between the abundance of these entities. Instead, we identified influential phages as being community hubs, suggesting phages influence 250 cancer by altering the greater bacterial community instead directly modulating the influential bacteria. Our previous work has shown that modifying colon bacterial communities with antibiotics alters colorectal 252 cancer progression and tumor burden in mice (19). This provides a precident for phage indirectly influencing colorectal cancer progression y altering the bacterial community composition. Overall our data supports 254 a model in which the bacteriophage community modulates the bacterial community, and through those interactions indirectly influences the bacteria driving colorectal cancer progression (Figure 4 A). Although our evidence suggests phages indirectly influence colorectal cancer development, we are not able to rule out 257 the role of phages directly interacting with the human host.

In addition to modeling the basic potential connections between virus communities, bacteria communities,

and colorectal cancer, we also used our data and existing knowledge of phage biology to develop a working hypothesis for the mechanisms by which this may occur. This was done by incorporating our findings into the Flynn model for colorectal cancer development (Figure 4 B) (18). We hypothesize that the broadly 262 infectious phages in the colon began lysing, and thereby disrupting, the bacterial communities to open a niche in which opportunistic bacteria (such as Fusobacterium nucleatum) were able to colonize. Once the 264 influential "driver" bacteria had established themselves in the epithelium, other opporunistic "passenger" bacteria were able to adhere to the driver, colonize, and begin establishing a biofilm. Phages may have played a role in biofilm dispersal and growth by lysing bacteria within the biofilm, a process shown to be important 267 for effective biofilm growth (28). The oncogenic bacteria were then able to transform the epithelial cells and 268 disrupt tight junctions to infiltrate the epithelium, thereby initiating an inflammatory immune response. As 269 the adenomatous polyps developed and progressed towards carcinogenesis, we observed a shift in the phages and bacteria important to our cancer classification model. As the bacteria entered their oncogenic synergy 271 with the epithelium, we hypothesize the phages could continue mediating biofilm dispersal, as well as support the colonized oncogenic bacteria by lysing competing cells to maintain the niche and provide nutrients to the 273 other bacteria. In addition to highlighting the most likely mechanisms by which the colorectal cancer virome 274 is interacting with the bacterial communities, this outline will guide the future, mostly functional studies, by 275 our group and others, into the role the virome plays in colorectal cancer. 276

A notable observation from our analysis was the lack of performance observed using bacterial metagenomic methods compared to the performance of models using viral metagenomes or 16S rRNA gene sequences. This 278 observation highlights the importance of high sequencing coverage in bacterial metagenomic studies, and the advantage of 16S rRNA over whole metagenomic shotgun sequencing. We found that there were six 280 bacterial OTUs that drove the performance of the 16S rRNA classification model, and these OTUs were all 281 sparsely present and lowly abundant. Filtration of OTUs with a median relative abundance of zero resulted 282 in the removal of the six important OTUs and reduced model performance to being nearly random like the 283 bacterial metagenomic model. The bacterial metagenomic OGUs represented only the most abundant taxa, 284 which was uninformative for this application. There has been some success in using shotgun metagenomic 285 approaches for stool colorectal cancer classification, but these approaches did not utilize OGU clustering like we did here, and the models only performed as well as the 16S rRNA model (29). Thus the targeted 287 16S rRNA sequencing approach, which yielded only a fraction of the bacterial metagenomic sequences, was more effective for detecting colorectal cancer in stool samples. Despite a loss of enthusiasm for 16S rRNA 289 gene sequencing in favor of shotgun metagenomic techniques, 16S rRNA gene sequencing is still a superior 290 methodological approach for some important applications. 291

In addition to the therapeutic ramifications for understanding the colorectal cancer microbiome, our findings provide a proof-of-principle that viruses, while under-appreciated and understudied in the human microbiome, are an important contributer to human disease that has the potential to provide an abundance of information that supplements that of bacterial communities. Evidence has suggested that the virome is a crucial component to the microbiome and that bacteriophages are important players. Bacteriophage and bacterial communities cannot thrive without each other (6). Not only is the human virome an important part of human health and disease, but it appears to have a particular significance in cancer research.

### 299 Methods

### Analysis Source Code & Availability

All associated source code and Makefile are available for review at the following GitHub repository:

https://github.com/SchlossLab/Hannigan-2016-ColonCancerVirome.

### 303 Study Design and Patient Sampling

This study was approved by the University of Michigan Institutional Review Board and all subjects provided informed consent. Design and sampling of this sample set have been reported previously (8). Briefly, whole evacuated stool was collected from patients who were 18 years of age or older, able to provide informed consent, have had colonoscopy and histologically confirmed colonic disease status, had not had surgery, had not had chemotherapy or radiation, and were free of known co-morbidities including HIV, chronic viral hepatitis, HNPCC, FAP, and inflammatory bowel disease. Samples were collected from four locations: Toronto (Ontario, Canada), Boston (Massachusetts, USA), Houston (Texas, USA), and Ann Arbor (Michigan, USA). Ninety patients were recruited to the study, thirty of which were designated healthy, thirty with detected adenomas, and thirty with detected carcinomas.

#### 16S Data Acquisition & Processing

The 16S rRNA gene sequences associated with this study were previously reported (8). Sequence (fastq) and metadata files were downloaded from http://www.mothur.org/MicrobiomeBiomarkerCRC. The 16S rRNA gene sequences were analyzed as described previously, relying on the Mothur analytical toolkit (v1.37.0) (30, 31). Briefly, the sequences were de-replicated, screened for chimeras using UCHIME (32) and the

- 318 SILVA database (33), and binned into operational taxonomic units (OTUS) using a 97% similarity threshold.
- Abundance was normalized for uneven sequencing depth by randomly sub-sampling to 10,000 sequences, as
  previously reported (20).

### Whole Metagenomic Library Preparation & Sequencing

DNA was extracted from stool samples using the PowerSoil-htp 96 Well Soil DNA Isolation Kit (Mo Bio Laboratories) using an EPMotion 5075 pipetting system. Purified DNA was used to prepare a shotgun sequencing library using the Illumina Nextera XT library preparation kit according to the standard kit protocol. The tagmentation time was increased from five minutes to ten minutes to improve DNA fragment length distribution. The library was sequenced using one lane of the Illumina HiSeq4000 platform and yielded 125 bp paired end reads.

### Virus Metagenomic Library Preparation & Sequencing

Genomic DNA was extracted from purified virus-like particles (VLPs) from stool samples, using a modified 329 version of a previously published protocol (25). Briefly, an aliquot of stool (~0.1g) was resuspended in SM buffer and vortexed to facilitate resuspension. The resuspended stool was centrifuged to remove major 331 particulate debris, followed by filtering through a 0.22µm filter to remove smaller contaminants. The filtered 332 supernatant was treated with chloroform to lyse contaminating cells including bacteria, human, fungi, etc. 333 The exposed genomic DNA from the lysed cells was degraded by treating the samples with DNase. The DNA 334 was extracted from the purified VLPs using the Wizard PCR Purification Preparation Kit (Promega). Disease 335 classes were staggered across purification runs to prevent run variation as a confounding factor. Purified DNA was used to prepare a shotgun sequencing library using the Illumina Nextera XT library preparation 337 kit according to the standard kit protocol. The tagmentation time was increased from five minutes to ten 338 minutes to improve DNA fragment length distribution. The PCR cycle number was increased from twelve to eighteen cycles to address the low biomass of the samples, as has been described previously (25). The library 340 was sequenced using one lane of the Illumina HiSeq4000 platform and yielded 125 bp paired end reads.

### 342 Metagenome Quality Control

- Both the viral and whole metagenomic sample sets were subjected to the same quality control procedures.
- The sequences were obtained as de-multiplexed fastq files from the HiSeq platform and subjected to 5' and 3'

adapter trimming using the CutAdapt program (v1.9.1) with an error rate of 0.1 and an overlap of 10 (34).

The FastX toolkit (v0.0.14) was used to quality trim the reads to a minimum length of 75bp and a minimum quality score of 30 (35). Reads mapping to the human genome were removed using the DeconSeq algorithm (v0.4.3) and default parameters (36).

### Contig Assembly & Abundance

Contigs were assembled using paired end read files that were purged of sequences without a corresponding pair (e.g. One read removed due to low quality). The Megahit program (v1.0.6) was used to assemble contigs 351 for each sample using a minimum contig length of 1000 bp and iterating assemblies from 21-mers to 101-mers by 20 (37). Contigs from the virus and whole metagenomic sample sets were concatenated within their 353 respective groups. Abundance of the contigs within each sample was calculated by aligning sequences back to the concatenated contig files using the bowtie2 global aligner (v2.2.1), with a 25 bp seed length and an 355 allowance of one mismatch (38). Abundance was corrected for contig reference length and the number of contigs included in each operational genomic unit. Abundance was also corrected for uneven sampling depth 357 by randomly sub-sampling virone and whole metagenomes to 1e6 and 5e5 reads, respectively, and removing 358 samples with less total samples than the threshold. Thresholds were set for maximizing sequence information 350 while minimizing numbers of lost samples.

### 361 Operational Genomic Unit Classification

Much like operational taxonomic units (OGUs) are used as an operational definition of similar 16S rRNA gene sequences in absence of taxonomic identification, we operationally defined closely related contig sequences as operational genomic units (OGUs) in the absence of taxonomic identity. OGUs were defined with the CONCOCT algorithm (v0.4.0) which bins related contigs by similar tetra-mer and co-abundance profiles within samples using a variational Bayesian approach (39). CONCOCT was used with a length threshold of 1000 bp for virus contigs and 2000 bp for bacteria due to computational limitations.

#### 368 Diversity

Alpha and beta diversity were calculated using the operational genomic unit abundance profiles for each sample. Sequences were rarefied to 100,000 sequences. Samples with less than the cutoff were removed from the analysis. Alpha diversity was calculated using the Shannon Entropy and Richness metrics. Beta diversity

was calculated using the Bray-Curtis metric (mean of 25 random sub-sampling iterations), and the statistical significance between the disease state clusters was assessed using an analysis of similarity (Anosim) with a post-hoc multivariate Tukey test. All diversity calculations were performed in R using the Vegan package [(40).

### 376 Classification Modeling

Classification modeling was performed in R using the Caret package (41). OTU and OGU abundance data 377 was preprocessed by removing features (OTUs and OGUs) that were present in less than half of the samples. 378 This served both as an effective feature reduction technique and made the calculations computationally 379 feasible. The binary random forest model was trained using the Area Under the ROC Curve (AUC) and 380 the three-class random forest model was trained using the mean AUC. Both were validated using five-fold cross validation. Each training set was repeated five times, and the model was tuned across five iterations 382 of mtry values. For consistency and accurate comparison between feature groups (e.g. bacteria, virus), the sample model parameters were used for each group. The maximum AUC during training was recorded 384 across 10 iterations of each group model creation to test the significance of the differences between feature 385 set performance. Statistical significance was evaluated using a Wilcoxon test between two categories, or a pairwise Wilcoxon test with Bonferroni corrected p-values when comparing more than two categories. 387

#### Taxonomic Identification of Operational Genomic Units

Viral operational genomic units (OGUs) were identified using a reference database consisting of all bacteriophage and eukaryotic virus genomes present in the European Nucleotide Archives. The longest contiguous
sequence in each operational genomic unit was used as a representative sequence for classification. Each
representative sequence was aligned to the reference genome database using the tblastx alignment algorithm
(v2.2.27) and a strict similarity threshold (e-value < 1e-25) (42). Annotation was interpreted as phage,
eukaryotic virus, or unknown.

#### Ecological Network Analysis & Correlations

The ecological network of the bacterial and phage operational genomic units were constructed and analyzed
as previously described (cite network preprint here). Briefly, a random forest model was used to predict
interactions between bacterial and phage genomic units, and those interactions were recorded in a graph

database using neo4j graph databasing software (v2.3.1). The degree of phage centrality was quantified using the alpha centrality metric in the igraph CRAN package. A Spearman correlation was performed between model importance and phage centrality scores.

### Phage Replication Style Identification

401

Phage OGU replication sytle was identified using methods described previously (25, 26, 43). Briefly, we identified lysogenic phage OGUs as representative contigs containing at least one of three genomic markers: 404 1) phage integrase genes, 2) prophage genes from the ACLAME database, 3) genomic similarity to bacterial 405 reference genomes. Integrase genes were identified in phage OGU representative contigs by aligning the contigs to a reference database of all known phage integrase genes from the Uniprot database (Uniprot 407 search term: "organism:phage gene:int NOT putative"). Prophage genes were identified in the same way, using the ACLAME set of reference prophage genes. In both cases, the blastx algorithm was used with an 409 e-value of 10e-5. Representative contigs were also identified as potential lysogenic phages by having a high genomic similarity to bacterial genomes. To accomplish this, representative phage contigs were aligned to the 411 European Nucleotide Archive bacterial genome reference set using the blastn algorithm (e-value < 10e-25). 412

### Conflicts of Interest

The authors declare no conflicts of interest.

# Acknowledgments

We thank the members of the Schloss lab for their underlying contributions. GD Hannigan was supported in part by the Michigan Molecular Mechanisms of Microbial Pathogenesis Fellowship.

# Figures Figures

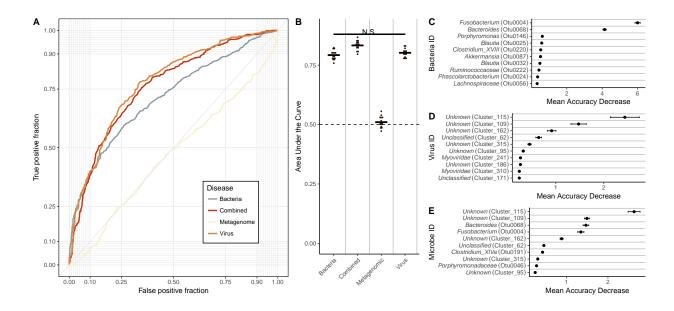

Figure 1: Results from healthy vs cancer classification models built using virome signatures, bacterial 16S signatures, whole metagenomic signatures, and a combination of virome and 16S signatures. A) ROC curve for visualizing the performance of each of the models for classifying stool as coming from either a cancerous or healthy individual. B) Quantification of the AUC variation for each model, and how it compares to each of the other models based on 15 iterations. A pairwise Wilcoxon test with a Bonferroni multiple hypothesis correction demonstrated that all models are significantly different from each other (p-value < 0.01). C) Mean decrease in accuracy (measurement of importance) of each operational taxonomic unit within the 16S classification model when removed from the classification model. Results based on 25 iterations. OTU features are colored by taxonomic identity. D) Mean decrease in accuracy of each operational genomic unit in the virome classification model. E) Mean decrease in accuracy of each operational genomic unit and operational taxonomic unit in the model using both 16S and virome features.

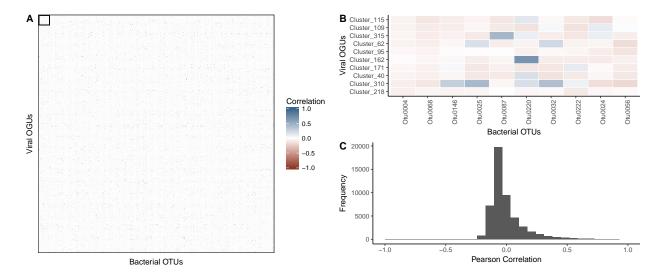

Figure 2: Relative abundance correlations between bacterial OTUs and virone OGUs. A) Pearson correlation coefficient values between all bacterial OTUs (x-axis) and viral OGUs (y-axis) with blue being positively correlated and red being negatively correlated. Operational units are organized by importance in their colorectal cancer classification models, such that the most important units are in the top left corner. B) Magnification of the boxed region in pannel (A), highlighting the correlation between the most important bacterial OTUs and virone OGUs. The most important operational units are in the top left corner of the heatmap, and the correlation scale is the same as pannel (A). C) Histogram quantifying the frequencies of Pearson correlation coefficients between all bacterial OTUs and virone OGUs.

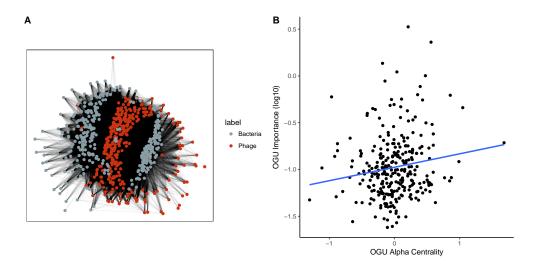

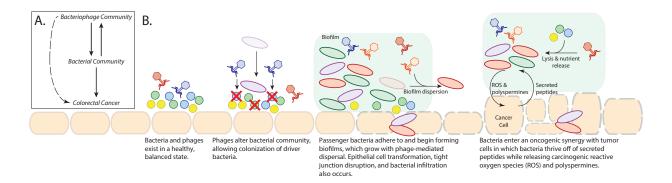

Figure 3: Community network analysis utilizing predicted interactions between bacteria and phage operational genomic units. A) Visualization of the community network for our colorectal cancer cohort. B) Scatter plot illustrating the correlation between importance (mean decrease in accuracy) and the degree of centrality for each OGU. A linear regression line was fit to illustrate the correlation (blue) which was found to be statistically significantly and weakly correlated (p-value = 0.0173, r = 0.14).

# <sup>419</sup> Supplemental Figures

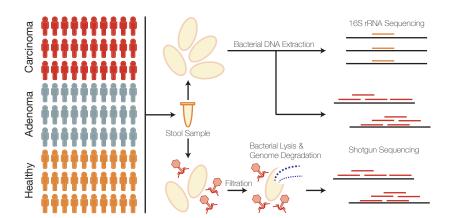

Figure S1: Cohort and sample processing outline. Thirty subject stool samples were collected from healthy, adenoma (pre-cancer), and carcinoma (cancer) patients. Stool samples were split into two aliquots, the first of which was used for bacterial sequencing and the second which was used for virus sequencing. Bacterial sequencing was done using both 16S rRNA amplicon and whole metagenomic shotgun sequencing techniques. Virus samples were purified for viruses using filtration and a combination of chloroform (bacterial lysis) and DNase (exposed genomic DNA degradation). The resulting encapsulated virus DNA was sequenced using whole metagenomic shotgun sequencing.

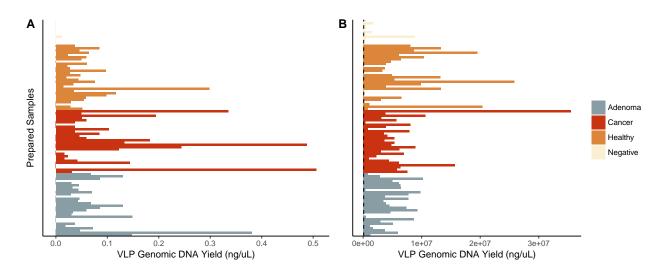

Figure S2: Basic Quality Control Metrics. A) VLP genomic DNA yield from all sequenced samples. Each bar represents a sample which is grouped and colored by its associated disease group. B) Sequence yield following quality control including quality score filtering and human decontamination.

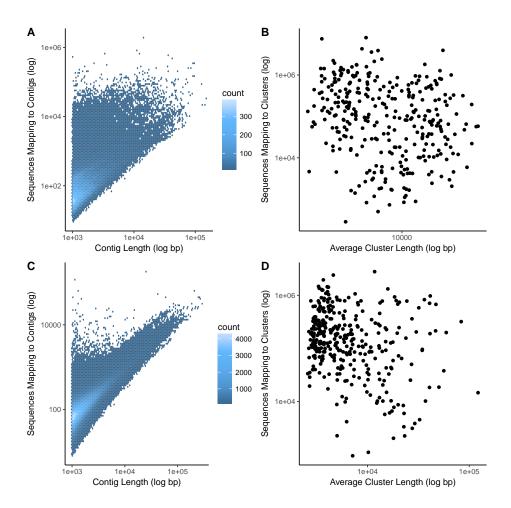

Figure S3: Length and coverage statistics. A) Heated scatter plot demonstrating the distribution of contig coverage (number of sequences mapping to each contig) and contig length for the virus metagenomic sample set. B) Scatter plot illustrating the distribution of operational genomic unit (OGU) length and sequence coverage for the virus metagenomic sample set. C) Heated scatter plot demonstrating the distribution of contig coverage and length for the whole metagenomic sample set. D) Scatter plot illustrating the distribution of operational genomic unit (OGU) length and sequence coverage for the whole metagenomic sample set.

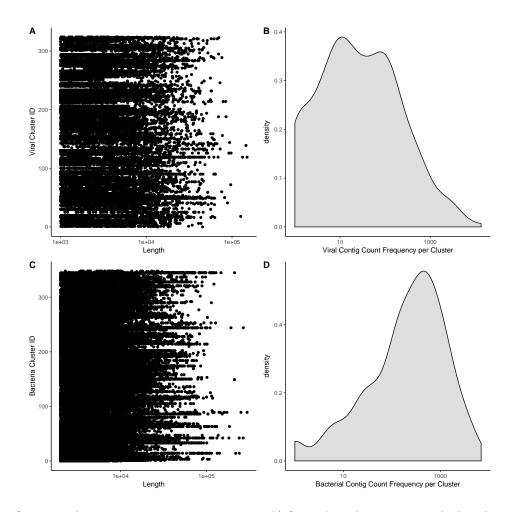

Figure S4: Operational genomic unit composition stats. A) Strip chart demonstrating the length and frequency of contigs within each operational genomic unit of the virone sample set. The y-axis is the operational genomic unit identifier, and x-axis is the length of each contig, and each dot represents a contig found within the specified operational genomic unit. B) Density plot (analogous to histogram) of the number of virone operational genomic units containing the specific number of contigs, as indicated by the x-axis. C-D) Sample plots as panels C and D, but for the whole metagenomic sample set.

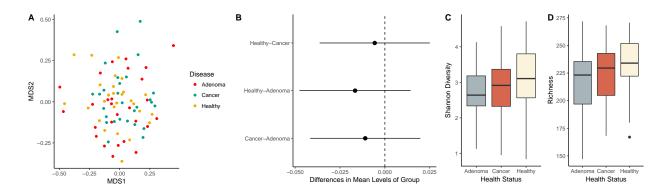

Figure S5: Diversity calculations comparing cancer states of the colorectal virone, based on relative abundance of operational genomic units in each sample. A) NMDS ordination of community samples, colored for cancerous (green), pre-cancerous (red), and healthy (yellow). B) Differences in means between disease group centroids with 95% confidence intervals based on an Anosim test with a post hoc multivariate Tukey test. Comparisons (indicated on y-axis) in which the intervals cross the zero mean difference line (dashed line) were not significantly different. C) Shannon diversity and D) richness alpha diversity quantification comparing pre-cancerous (grey), cancerous (red), and healthy (tan) states.

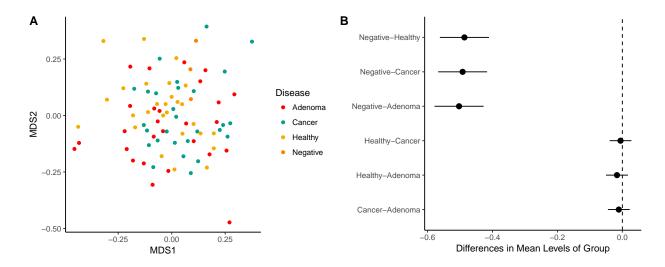

Figure S6: Beta-diversity comparing disease states and the study negative controls. A) NMDS ordination of community samples, colored by disease state. B) Differences in means between disease group centroids with 95% confidence intervals based on an Anosim test with a post hoc multivariate Tukey test. Comparisons in which the intervals cross the zero mean difference line (dashed line) were not significantly different.

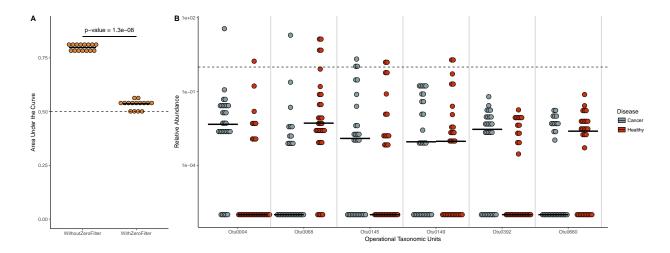

Figure S7: Comparison of bacterial 16S rRNA classification models with and without OTUs whose median relative abundance are greater than zero. A) Classification model performance (measured as area under the curve) for bacteria models using 16S rRNA data both with and without filtering of samples whose median was zero. Significance was calculated using a Wilcoxon rank sum test, and the resulting p-value is shown. The random area under the curve (0.5) is marked with a dashed line. B) Relative abundance of the six bacterial OTUs removed when filtered for OTUs with median relative abundance of zero. OTU relative abundance is seperated by healthy (red) and cancerous (grey) samples. Relative abundance of 1% is marked by the dashed line.

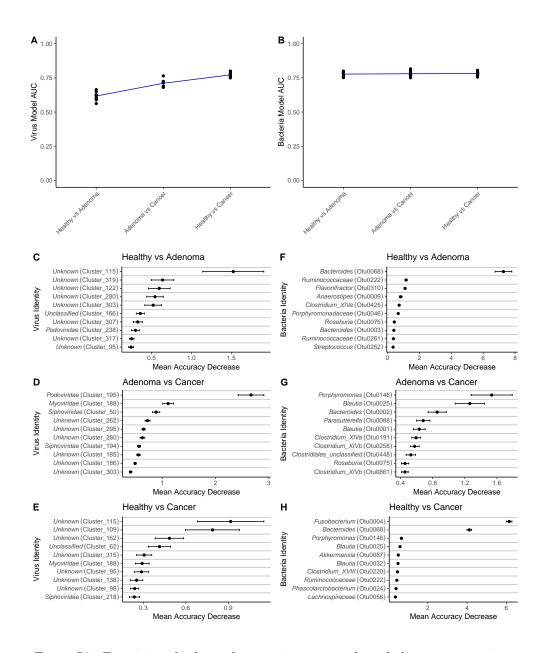

Figure S8: Transition of colorectal cancer importance through disease progression.

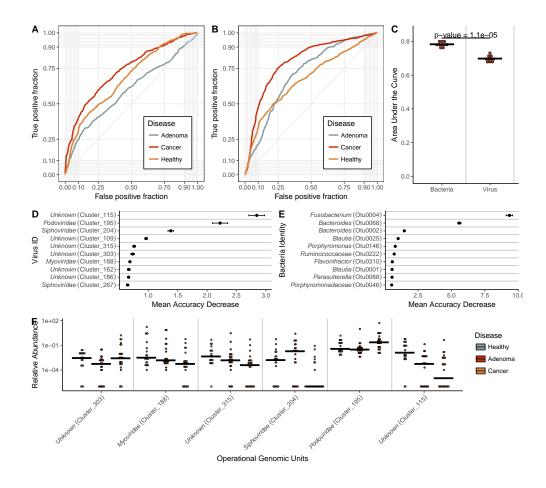

Figure S9: ROC curves from A) virone and B) bacterial 16S three-class random forest models tuned on mean AUC. Each curve represents the ability of the specified class to be classified against the other two classes. C) Quantification of the mean AUC variation for each model based on 10 model iterations. A pairwise Wilcoxon test with a Bonferroni multiple hypothesis correction demonstrated that the models are significantly different (alpha = 0.01). D) Mean decrease in accuracy when virone operational genomic units and E) bacterial 16S E0 E1 or E2 E3 are removed from the respective three-class classification models. Results based on 25 iterations. E3 E4 E4 Relative abundance of the six most important virone E5 of E6 in the model, with the most important on the right. Line indicates abundance mean.

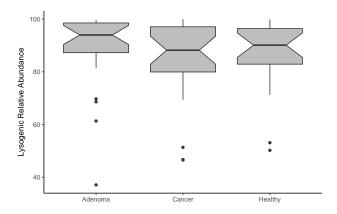

Figure S10: Lysogenic phage relative abundance in disease states. Phage OGUs were predicted to be either lytic or lysogenic, and the relative abundance of lysogenic phages was quantified and represented as a boxplot. No disease groups were statistically significant.
